NCL30073

Current-Mode PWM Controller for LED Application

The NCL30073 is a highly integrated PWM controller capable of delivering a rugged and high performance LED converter in a tiny TSOP–6 package. With a supply range up to 24 V, the controller hosts a 65 kHz switching circuitry operated in peak current mode control. When the voltage on FB pin decreases, the controller enters skip cycle while limiting the peak current.

Over Power Protection (OPP) is a difficult exercise especially when no–load standby requirements drive the converter specifications. The ON proprietary integrated OPP lets you harness the maximum delivered power without affecting your standby performance simply via two external resistors. An Over Voltage Protection is also combined on the same pin but also on the VCC line. They offer an efficient protection in case of adverse open loop operation.

Finally, a timer–based short–circuit protection offers the best protection scheme, letting you precisely select the protection trip point without caring of a loose coupling between the auxiliary and the power windings.

Features

• Fixed–frequency 65 kHz Current–mode Control Operation
• Internal and Adjustable Over Power Protection (OPP) Circuit
• Internal Ramp Compensation
• Internally Fixed 4 ms Soft–start
• 115 ms Timer–based Auto–recovery Short–circuit Protection
• Protection – Autorecovery
  ♦ OVP by VCC
  ♦ OIP
  ♦ OTP – Foldback
  ♦ Short Circuit
• Up to 24 V VCC Operation
• Extremely Low No–load Standby Power
• Isolated and Non–isolated Outputs
• Good Regulation – 5%
• High Power Factor > 0.9
• Single Winding Inductor
• Low Parts Count
• EPS 2.0 Compliant
• Pb–Free Devices
• +300 mA/–500 mA Source/Sink Drive Capability

Typical Application

• Dimmable Retrofit and Low Power Fixture LED Applications
• Phase Cut Dimmer Compatible – LE or TE Types
• Multiple Topology Support
  ♦ Buck
  ♦ Buck Boost
  ♦ Flyback

Stresses exceeding those listed in the Maximum Ratings table may damage the device. If any of these limits are exceeded, device functionality should not be assumed, damage may occur and reliability may be affected.

1. The transient voltage is a voltage spike injected to DRV pin being in high state. Maximum transient duration is 100 ns.
2. See the Figure 4 for detailed specification of transient voltage.
3. This device contains latch–up protection and exceeds 100 mA per JEDEC Standard JESD78.

Introduction
NCL30073 implements a standard current mode architecture where the switch-off event is dictated by the peak current set point. This component represents the ideal candidate for LED applications. The NCL30073 packs all the necessary components normally needed in today modern LED converter designs, bringing several enhancements such as a non-dissipative OPP, OVP/OTP implementation, short-circuit protection, improved consumption, robustness and ESD capabilities.

- Current-mode Operation with Internal Slope Compensation:
  Implementing peak current mode control at a 65 kHz switching frequency, the NCL30073 offers an internal slope compensation signal that can easily be summed up to the sensed current. Sub harmonic oscillations can thus be fought via the inclusion of a simple resistor in series with the current-sense information.

- Internal OPP:
  By routing a portion of the negative voltage present during the on-time on the auxiliary winding to the dedicated OPP pin (pin 1), the user has a simple and non-dissipative means to alter the maximum peak current set point as the bulk voltage increases. If the pin is grounded, no OPP compensation occurs. If the pin receives a negative voltage, then a peak current is reduced down.

- Low Startup and Standby Current:
  Reaching a low no-load standby power always represents a difficult exercise when the controller draws a significant amount of current during startup.

- Skip Capability:
  A continuous flow of pulses is not desired in all application. The controller monitors FB pin voltage and when it reaches a level of $V_{\text{skip}}$, the controller enters skip-cycle mode, to reduce number of switching periods.

- Internal Soft-start:
  A soft-start precludes the main power switch from being stressed upon start-up. The soft-start duration is internally fixed for time $t_{\text{SS}}$ and it is activated during new startup sequence or during recovering after auto-recovery hiccup mode.

- Auto-recovery Input:
  The controller includes an OPP input (pin 1) that can be used to sense an over voltage or an over temperature event on the converter. If this pin is brought higher than the internal reference voltage $V_{\text{LATCH}}$ for four consecutive cycles, then the circuit enters into auto-recovery mode.

- Auto-recovery OVP on $V_{\text{CC}}$:
  An OVP protects the circuit against $V_{\text{CC}}$ runaways. If the fault is present at least for time $t_{\text{OVP(del)}}$ then the OVP is validated and the controller enters hiccup mode. When the $V_{\text{CC}}$ returns to a nominal level, the controller resumes operation.

- Short-circuit Protection:
  Short-circuit and especially overload protections are difficult to implement when a strong leakage inductance between auxiliary and power windings affects the transformer (the aux winding level does not properly collapse in presence of an output short). In this controller, every time the internal maximum peak current limit $V_{\text{limit}}$ is activated (or less when OPP is used), an error flag is asserted and a time period starts thanks to an internal timer. When the timer has elapsed while a fault is still present, the controller enters an auto-recovery mode.

Start-up Sequence
The NCL30073 start-up voltage is made purposely high to permit large energy storage in a small $V_{\text{CC}}$ capacitor value. This helps operate with a small start-up current which, together with a small $V_{\text{CC}}$ capacitor, will not hamper the start-up time. To further reduce the standby power, the start-up current of the controller is extremely low, below 10 $\mu$A. The start-up resistor can therefore be connected to the bulk capacitor or directly to the mains input voltage to further reduce the power dissipation.
The first step starts with the calculation of the needed VCC capacitor which will supply the controller which it operates until the auxiliary winding takes it over. Experience shows that this time \( t_1 \) can be between 5 and 20 ms. If we consider we need at least an energy reservoir for a \( t_1 \) time of 10 ms, the VCC capacitor must be larger than:

\[
C_{VCC} \geq \frac{1.6m \cdot 10m}{18 - 8.9} \geq 1.7 \mu F
\]  
(eq. 1)

Let us select a 2.2 \( \mu F \) capacitor at first and experiments in the laboratory will let us know if we were too optimistic for the time \( t_1 \). The VCC capacitor being known, we can now evaluate the charging current we need to bring the VCC voltage from 0 V to the \( V_{CC(on)} \) of the IC. This current has to be selected to ensure a start-up at the lowest mains (85 Vrms) to be less than 200 ms (acceptable time):

\[
I_{charge} \geq \frac{V_{CC(on)} \cdot C_{VCC}}{t_{start-up}} \geq \frac{18 \cdot 2.2 \mu A}{0.1} \geq 198 \mu A
\]  
(eq. 2)

If we account for the 10 \( \mu A \) (maximum) that will flow to the controller, then the total charging current delivered by the start-up resistor must be 208 \( \mu A \). If we connect the start-up network to the mains (half-wave connection then), we know that the average current flowing into this start-up resistor will be the smallest when \( V_{CC} \) reaches the \( V_{CC(on)} \) of the controller:

\[
I_{CVCC,min} = \frac{V_{ac, rms}}{2R_{start-up}} \geq \frac{85,2}{2 \cdot 97 k\Omega}
\]  
(eq. 3)

To make sure this current is always greater than 346 \( \mu A \), then, the minimum value for \( R_{start-up} \) can be extracted:

\[
R_{start-up} \leq \frac{2 \cdot V_{ac, rms}}{I_{CVCC(min)}} \leq \frac{85,2}{208 \mu A} \leq 97 k\Omega
\]  
(eq. 4)

This calculation is purely theoretical, considering a constant charging current. In reality, the take over time can be shorter (or longer!) and it can lead to a reduction of the VCC capacitor. Thus, a decrease in charging current and an increase of the start-up resistor can be experimentally tested, for the benefit of standby power. Laboratory experiments on the prototype are thus mandatory to fine tune the converter. If we chose the 92 k\( \Omega \) resistor as suggested by Eq. 4, the dissipated power at high line amounts to:

\[
P_{R_{start-up,max}} = \frac{V_{ac,peak}^2}{4 \cdot R_{start-up}} = \frac{(230 \cdot \sqrt{2})^2}{4 \cdot 92k\Omega} = 287 mW
\]  
(eq. 5)

Now that the first VCC capacitor has been selected, we must ensure that the self-supply does not disappear when in no-load conditions. In this mode, the skip-cycle can be so deep that refreshing pulses are likely to be widely spaced, inducing a large ripple on the VCC capacitor. If this ripple is too large, chances exist to touch the \( V_{CC(min)} \) and reset the controller into a new start-up sequence. A solution is to grow this capacitor but it will obviously be detrimental to the start-up time. The option offered in Figure 38 elegantly solves this potential issue by adding an extra capacitor on the auxiliary winding. However, this component is separated from the VCC pin via a simple diode. You therefore have the ability to grow this capacitor as you need to ensure the self-supply of the controller without affecting the start-up time and standby power.

**Internal Over Power Protection**

There are several known ways to implement Over Power Protection (OPP), all suffering from particular problems. These problems range from the added consumption burden on the converter or the skip-cycle disturbance brought by the current-sense offset. A way to reduce the power capability at high line is to capitalize on the negative voltage
swing present on the auxiliary diode anode. During the turn-on time, this point dips to \(-N_2V_{\text{bulk}}\), where \(N_2\) being the turns ratio between the primary winding and the auxiliary winding. The negative plateau observed on Figure 39 will have amplitude depending on the input voltage. The idea implemented in this chip is to sum a portion of this negative swing with the internal voltage reference \(V_{\text{limit}} = 0.8\) V. For instance, if the voltage swings down to \(-150\) mV during the on-time, then the internal peak current set point will be fixed to the value \(0.8\) V – \(0.150\) V = \(650\) mV. The adopted principle appears in Figure 40 and shows how the final peak current set point is constructed.

Let’s assume we need to reduce the peak current from \(2.5\) A at low line, to \(2\) A at high line. This corresponds to a \(20\%\) reduction or a set point voltage of \(640\) mV. To reach this level, then the negative voltage developed on the OPP pin must reach:

\[
V_{\text{OPP}} = 0.8 \cdot V_{\text{limit}} - V_{\text{limit}} = 0.64 - 0.8 = -160\text{ mV} \quad \text{(eq. 6)}
\]

Figure 39. The Signal Obtained on the Auxiliary Winding Swings Negative During the On–time

Figure 40. The OPP Circuitry Affects the Maximum Peak Current Set Point by Summing a Negative Voltage to the Internal Voltage Reference

www.onsemi.com
The OPP pin is surrounded by Zener diodes stacked to protect the pin against ESD pulses. These diodes accept some peak current in the avalanche mode and are designed to sustain a certain amount of energy. On the other side, negative injection into these diodes (or forward bias) can cause substrate injection which can lead to an erratic circuit behavior. To avoid this problem, the pin is internal clamped slightly below –300 mV which means that if more current is injected before reaching the ESD forward drop, then the maximum peak reduction is kept to 40%. If the voltage finally forward biases the internal zener diode, then care must be taken to avoid injecting a current beyond –2 mA.

Finally, please note that another comparator internally fixes the maximum peak current set point to value $V_{\text{limit}}$ even if the OPP pin is adversely biased above 0 V.

**Short–Circuit Protection**

In case of output short–circuit or if the LED converter experiences a severe overloading situation, an internal error flag is raised and the fault timer starts countdown. If the UVLO has come (see Figure 41 – Short–circuit case I.) or the error flag is asserted throughout the $t_{\text{fault}}$ time (see Figure 41 – Short–circuit case II.) – i.e. the fault timer has elapsed, the driving pulses are stopped and the $V_{\text{CC}}$ falls down as the auxiliary voltage are missing. When the supply voltage $V_{\text{CC}}$ touches the $V_{\text{CC(min)}}$ level, the controller consumption is down to a few $\mu\text{A}$ and the $V_{\text{CC}}$ slowly builds up again thanks to the resistive startup network. When $V_{\text{CC}}$ reaches $V_{\text{CC(on)}}$, the controller enter into start–up cycle. Please note that soft–start is activated upon every re–start attempt.

*Figure 41. An Auto–recovery Description*
Slope Compensation

The NCL30073 includes an internal slope compensation signal. This is the buffered oscillator clock delivered during the on–time only. Its amplitude is around 2.5 V at the maximum duty ratio. Slope compensation is a known means used to cure sub harmonic oscillations in CCM–operated current–mode converters. These oscillations take place at half the switching frequency and occur only during Continuous Conduction Mode (CCM) with a duty ratio greater than 50%. To lower the current loop gain, one usually injects between 50 and 100% of the primary inductance downslope. Figure 42 depicts how the ramp is generated internally. Please note that the ramp signal will be disconnected from the CS pin during the off–time.

![Diagram of slope compensation](image)

**Figure 42. Inserting a Resistor in Series with the Current Sense Information Brings Slope Compensation and Stabilizes the Converter in CCM Operation**

In the NCL30073 controller, the oscillator ramp features a 2.5 V swing. If the clock operates at a 65 kHz frequency, then the available oscillator slope corresponds to:

\[
S_{\text{ramp}} = \frac{V_{\text{ramp, peak}}}{D_{\text{max}} \cdot T_{\text{SW}}} = \frac{2.5}{0.8 \cdot 15\mu s} = 208 \text{ mV/µs}
\]  (eq. 7)

In a flyback design, let’s assume that our primary inductance \(L_p\) is 770 µH, and the SMPS delivers 19 V with a \(N_p/N_s\) ratio of 1:0.25. The off–time primary current slope \(S_p\) is thus given by:

\[
S_p = \left(\frac{V_{\text{out}} + V_i}{L_p}\right) \cdot \frac{N_s}{N_p} = \left(\frac{19 + 0.7}{770\mu H}\right) \cdot 4 = 102 \text{ mA/µs}
\]  (eq. 8)

Given a sense resistor of 330 mΩ, the above current ramp turns into a voltage ramp of the following amplitude:

\[
S_{\text{sense}} = S_p \cdot R_{\text{sense}} = 102\text{ m} \cdot 0.33 = 34 \text{ mV/µs}
\]  (eq. 9)

If we select 50% of the downslope as the required amount of slope compensation, then we shall inject a ramp whose slope is 17 mV/µs. Our internal compensation being 208 mV/µs, the divider ratio \((\text{divratio})\) between \(R_{\text{comp}}\) and the internal \(R_{\text{ramp}} = 20 \text{ kΩ}\) resistor is:

\[
\text{divratio} = \frac{0.5 \cdot S_{\text{sense}}}{S_{\text{ramp}}} = 0.082
\]  (eq. 10)

The series compensation resistor value is thus:

\[
R_{\text{comp}} = R_{\text{ramp}} \cdot \text{divratio} = 20\text{ k} \cdot 0.082 = 1.64 \text{ kΩ}
\]  (eq. 11)

A resistor of the calculated value will then be inserted from the sense resistor to the current sense pin. We recommend adding a small capacitor of 100 pF, from the current sense pin to the controller ground for an improved immunity to the noise. Please make sure both components are located very close to the controller.
**Protection Pin**

The OPP pin not only allows a reduction of the peak current set point in relationship to the line voltage, it also offers a means to enter the auto−recovery mode.

The auto−recovery detection is made by observing the OPP pin by a comparator featuring a $V_{\text{latch}}$ reference voltage. However, for noise reasons and in particular to avoid the leakage inductance contribution at turn off, a blanking delay $t_{\text{latch-blank}}$ is introduced before the output of the OVP comparator is checked. Then, the OVP comparator output is validated only if its high−state duration lasts for a minimum time $t_{\text{latch-del}}$. Below this value, the event is ignored. Then, a counter ensures that only 4 successive OVP events have occurred before actually auto−recovery mode is triggered. There are several possible implementations, depending on the needed precision and the parameters you want to control.

The first and easiest solution is the additional resistive divider on top of the OPP one. This solution is simple and inexpensive but requires the insertion of a diode to prevent disturbing the OPP divider during the on−time.

![Figure 43. Auto−recovery of the Controller and Resuming Operation](image)

![Figure 44. A Simple Resistive Divider Brings the OPP Pin above 3 V in case of a $V_{\text{CC}}$ Voltage Runaway above 18 V](image)
First, calculate the OPP network with the above equations. Then, suppose we want to trigger auto−recovery of our controller when $V_{out}$ exceeds 25 V. On the auxiliary winding, the plateau reflects the output voltage by the turns ratio between the power and the auxiliary winding. In case of voltage runaway for 19 V output, the plateau will go up to:

$$V_{aux,OVP} = V_{out} \cdot \frac{N_s}{N_{aux}} = 25 \cdot \frac{0.18}{0.25} = 18 \text{V}$$  \hspace{1cm} (eq. 12)

Since our OVP comparator trips at level $V_{latch} = 3 \text{V}$, across the 1 k\Omega selected OPP pull−down resistor, it implies a 3 mA current. From 3 V to go up to 18 V, we need an additional 15 V. Under 3 mA and neglecting the series diode forward drop, it requires a series resistor of:

$$R_{OVP} = \frac{V_{out}}{\frac{V_{aux,OVP} - V_{latch}}{R_{OPL}}} = \frac{18 - 3}{3/1k} = 5 \text{k}\Omega$$  \hspace{1cm} (eq. 13)

In nominal conditions, the plateau establishes to around 14 V. Given the divide by 6 ratio, the OPP pin will swing to 14/6 = 2.3 V during normal conditions, leaving 700 mV for the noise immunity. A 100 pF capacitor can be added to improve it and avoid erratic trips in presence of external surges. Do not increase this capacitor too much otherwise the OPP signal will be affected by the integrating time constant.

A second solution for the OVP detection alone is to use a Zener diode wired as recommended by Figure 45.

In this case, to still trip at 18 V level, we have selected a 15 V Zener diode. In nominal conditions, the voltage on the OPP pin is almost 0 V during the off−time as the Zener is fully blocked. This technique clearly improves the noise immunity of the system compared to that obtained from a resistive string as in Figure 44. Please note the reduction of the capacitor on the OPP pin to 10−22 pF. This is because of the potential spike going through the Zener parasitic capacitor and the possible auxiliary level shortly exceeding its breakdown voltage during the leakage inductance reset period (hence the internal blanking delay $t_{latch−blank}$ at turn off). This spike despite its very short time is energetic enough to charge the added capacitor $C_1$ and given the time constant, could make it discharge slower, potentially disturbing the blanking circuit. When implementing the Zener option, it is important to carefully observe the OPP pin voltage (short probe connections!) and check that enough margin exists to that respect.
Over Temperature Protection

In a lot of designs, the converter must be protected against thermal runaways, e.g. when the temperature inside the converter box increases a certain value. Figure 46 shows how to implement a simple OTP using an external NTC and a series diode. The principle remains the same: make sure the OPP network is not bothered by the additional NTC hence the presence of this diode.

![Figure 46. The Internal Circuitry Hooked to OPP Pin can be used to Implement Over Temperature Protection (OTP)](image)

When the NTC resistor will diminish as the temperature increases, the voltage on the OPP pin during the off-time will slowly increase and, once it passes $V_{latch}$ level for 4 consecutive clock cycles, the controller will enter auto-recovery mode.

We have found that the plateau voltage on the auxiliary diode was 14 V in nominal conditions. We have selected an NTC which offers a 470 kΩ resistance at 25°C and drops to 8.8 kΩ at 110°C. If our auxiliary winding plateau is 14 V and we consider a 0.7 V forward drop for the diode, then the voltage across the NTC in fault mode must be:

$$V_{NTC} = V_{aux} - V_{latch} - V_F = 14 - 3 - 0.7 = 10.3 \text{ V}$$

(eq. 14)

Based on the 8.8 kΩ NTC resistor at 110°C, the current inside the device must be:

$$I_{NTC} = \frac{V_{NTC}}{R_{NTC(110)}} = \frac{10.3}{8.8} = 1.2 \text{ mA}$$

(eq. 15)

As such, the bottom resistor $R_{OPPL}$, can easily be calculated:

$$R_{OPPL} = \frac{V_{latch}}{I_{NTC}} = 2.5 \text{ kΩ}$$

(eq. 16)

Now the pull down OPP resistor is known, we can calculate the upper resistor value $R_{OPPU}$ to adjust the power limit at the chosen output power level. Suppose we need a 200 mV decrease from the $V_{limit}$ setpoint and the on-time swing on the auxiliary anode is −67.5 V, then we need to drop over $R_{OPPU}$ a voltage of:

$$V_{R_{OPPU}} = V_{aux} - V_{OPP} = -67.5 + 0.2 = -67.3 \text{ V}$$

(eq. 17)

The current circulating the pull down resistor $R_{OPPL}$ in this condition will be:

$$I_{R_{OPPL}} = \frac{V_{OPP}}{R_{OPPL}} = \frac{-0.2}{2.5k} = -80 \mu\text{A}$$

(eq. 18)

The $R_{OPPU}$ value is therefore easily derived:

$$R_{OPPU} = \frac{V_{R_{OPPU}}}{I_{R_{OPPU}}} = \frac{-67.3}{-80\mu} = 841 \text{ kΩ}$$

(eq. 19)
Combining OVP and OTP
The OTP and Zener–based OVP can be combined together as illustrated by Figure 47. In nominal V\textsubscript{CC}/output conditions, when the Zener is not activated, the NTC can drive the OPP pin and trigger the protection in case of a fault.

On the contrary, in nominal temperature conditions, if the loop is broken, the voltage runaway will be detected and acknowledged by the controller.

In case the OPP pin is not used for either OPP or OVP, it can simply be grounded.

Filtering the Spikes
The auxiliary winding is the seat of spikes that can couple to the OPP pin via the parasitic capacitances exhibited by the Zener diode and the series diode. To prevent an adverse triggering of the Over Voltage Protection circuitry, we recommend the installation of a small \textit{RC} filter before the detection network as illustrated by Figure 48. The values of resistance and capacitance must be selected to provide the adequate filtering function without degrading the stand–by power by an excessive current circulation.
