NCV8855

Quad-Output Automotive System Power Supply IC with Integrated High-Side 2A Switch

The NCV8855 is a multiple output controller / regulator IC with an integrated high-side load switch. The NCV8855 addresses automotive radio system and instrument cluster power supply requirements. In addition to the high-side load switch, the NCV8855 includes a switch-mode power supply (SMPS) buck controller, a 2.5 A SMPS buck regulator and two low dropout (LDO) linear regulator controllers. The NCV8855 in combination with the ultra-low quiescent current NCV861x IC forms an eight-output automotive radio or instrument cluster power solution. The NCV8855 has an internally set switching frequency of 170 kHz, with a SYNC pin for external frequency synchronization.

The NCV8855 is intended to supply power to various loads, such as a tuner, CD logic, audio processor and CD / tape control within a car radio. The high-side switch can be used for a CD / tape mechanism or switching an electrically-powered antenna or display unit. In an instrument cluster application, the NCV8855 can be used to power graphics display, flash memory and CAN transceivers. In addition, the high-side switch can be used to limit power to a TFT display during a battery over-voltage condition.

Features

- < 1 µA Shutdown Current
- Meets ES–XW7T–1A278–AB Test Pulse G – Loaded Conditions
- VIN Operating Range 9.0 to 18.0 V
- 1 SMPS Controller with Adjustable Current Limit
- 1 SMPS Regulator with Internal 300 mΩ NMOS Switch
- 2 LDO Controllers with Current Limit and Short Circuit Protection
- 1 High-side Load Switch with Internal 300 mΩ NMOS FET
- Adjustable Output Voltage for All Controllers / Regulators
- 800 mV, ±1% Reference Voltage
- System Enable Pin
- Single Enable Pin for Both LDO Controllers
- Independent Enable for High-side Load Switch
- Thermal Shutdown with Thermal Warning Indicator
- This is a Pb-Free Device

Applications

- Automotive Radio
- Instrument Cluster, Driver Information System (DIS)

THEORY OF OPERATION

Device Description

The NCV8855 is a multiple output controller/regulator IC with an integrated high-side load switch. The NCV8855 will address automotive radio system and instrument cluster power supply requirements. In addition to the high-side load switch, the NCV8855 comprise a switch-mode power supply (SMPS) buck controller, a 2 A SMPS buck regulator, and two low dropout linear regulator controllers (LDO). The NCV8855 in combination with the ultra-low Iq NCV861x IC forms an eight output automotive radio or instrument cluster power solution.

![Diagram](http://onsemi.com)

**Figure 17.**

The NCV8855 has an internally set switching frequency of 170 kHz and provides an SYNC pin for external frequency synchronization. The NCV8855 is designed to operate within the range of 9 V to 18 V. The switch-mode power supplies are voltage-mode controlled and the LDO controllers drive P-channel MOSFETs as pass devices.

**System Enable (SYS_EN)**

The system enable (SYS_EN) pin is used to start device operation or place it in low quiescent shutdown. Driving this pin high will allow the two main internal voltage rails (DRV_VPP and 5V_IC) to power up. These voltage rails require external bypassing and have independent UVLO trip points. Both rails must be operational in order for the IC to function. After exceeding its UVLO threshold, the IC will power up the switch-mode power supplies with a soft-start. Conversely, a logic-low on the pin will power down the DRV_VPP and 5V_IC rails and place the IC in an ultra-low current shutdown state.

**Linear Regulator Enable (LDO_EN)**

The low-dropout linear regulators (LDOs) have a dedicated enable pin. This pin controls the startup and shutdown of the LDOs. The SYS_EN pin must be logic high for this pin to function. It is possible to drive this pin high coincidently with SYS_EN, but the LDO outputs will not startup until DRV_VPP and 5V_IC have increased above its UVLO thresholds.

**High-Side Switch Enable (HS_EN)**

The high-side switch enable controls only the high-side switch. Similar to LDO_EN, the SYS_EN pin must be logic high for this pin to function. The voltage level on all enable pins have been designed to work with 3.3 V or 5 V logic.

**IC Power (VIN, VIN_SW, DRV_VPP, 5V_IC)**

There are many input voltage rails for the NCV8855. The main power supply input for the IC is VIN. The DRV_VPP, 5V_IC and the high-side switch drain are all driven from VIN. The DRV_VPP voltage rail is the power rail for SMPS1 & SMPS2’s gate driver circuits. The 5V_IC voltage rail is the main supply for the IC. The VIN_SW rail is the supply rail for SMPS2’s internal upper MOSFET. VIN_SW is directly tied to the drain of the N-channel MOSFET.

![Diagram](http://onsemi.com)

**Figure 18.**

Two additional inputs rails are ISNS1+ and ISNS2+. These inputs not only serve as the positive reference for the current sense circuit, but also serve as the supply rail for the LDO error amplifier.

**Startup and Shutdown Behavior**

The startup sequence primary depends on the system configuration. However, in every case, enable SYS_EN first. The SYNC pin must not be held at logic high before SYS_EN is enabled. Below shows typical startup and
shutdown behavior when VOUT3 is derived from VOUT1 (as shown in Figure 1).

![Figure 19.](http://onsemi.com)

In addition to the enable pins, the IC features an automatic shutdown during a high battery condition. When VIN exceeds 18.5 V (typ) the IC will shutdown all outputs. When VIN falls below 17.9 V (typ), the IC will go through a typical start up and resume normal operation.

### Out-of-Phase Synchronization

By default, the turn−on of SMPS2 is delayed by half the switching cycle, which corresponds to 180° phase delay. Advantages of out–of–phase synchronization are many. Interleaving the current pulses at the input reduces the input RMS current. This reduction minimizes the input filter requirement, allowing the use of smaller components, hence a more cost effective solution. In addition, since peak current is reduced, emitted EMI is also reduced.

### Synchronizing (SYNC)

Synchronizing the NCV8855 to an external frequency is achieved by providing a 10 to 90% duty cycle clock to the SSYNC pin. The rising edge of the clock signal will immediately reset the internal RAMP of SMPS2 and begin a new pulse for SMPS2. Conversely, the falling edge of the clock signal will immediately reset the internal RAMP of SMPS1 and begin a new pulse for SMPS1. The first rising edge of the external clock signal may cause a momentary phase diversion between SMPS1 and SMPS2, but will lock into desired phase on the subsequent falling edge. During start up, the SYNC pin must not be held at a logic high.

### Thermal Warning (HOT_FLG) and Thermal Shutdown

There are two thermal sensors in the NCV8855 devices. If any of these two exceeds the warning threshold, the HOT_FLG will assert low. In addition, if thermal monitor 1 (TMON_HSS) exceeds the warning threshold, the high−side switch current limit will fold back to 1.4 A (typ). If TMON_HSS exceeds its TSD point, the high−side switch will latch off while the other device functions will continue to operate. A HS_EN or SYS_EN toggle will be required to re−start the high−side switch in the case of a TMON_HSS TSD event.

If thermal monitor 2 (TMON_SW) exceeds it TSD point, the entire chip (regardless of the state of TMON_HSS) will latch off, and a SYS_EN toggle will be required to restart.

### Overcurrent Protection (SMPS1)

Overcurrent protection for SMPS1 is implemented via VDS(on) sensing of the upper MOSFET. At the beginning of each switching cycle, after a short blanking time, the voltage is sampled across the upper MOSFET and compared to the threshold set by ROCSET.

![Figure 20.](http://onsemi.com)

If this comparator is tripped, then the pulse is immediately halted. This operation repeats every cycle until the overcurrent condition is removed.

The over−current limit can be calculated with the following equation:

\[
I_{\text{LIMIT}} = \frac{R_{\text{OCSET}} \times I_{\text{OCSET}}}{R_{\text{DS(on)}}} \quad (\text{eq. 1})
\]

where, I_{OCSET} is 50 μA (typ.). To calculate the ROCSET value, the maximum R_{DS(on)} (at temperature) and the minimum value of I_{OCSET} must be used. In addition to this, the following relationship should be met:

\[
I_{\text{LIMIT}} \geq I_{\text{OUT1(MAX)}} + \frac{I_{pk-pk}}{2} \quad (\text{eq. 2})
\]

where IOUT1(MAX) is the maximum dc current allowed, and Ipk-pk/2 is the peak ripple current above the dc value. This will insure that undesirable trigger of the over−current protection is avoided.

To protect in the case of a short circuit event, a comparator monitoring the feedback voltage is incorporated. If the output voltage goes below 70% of nominal after start−up, the part is latched off, requiring SYS_EN to be toggled to restart the part.

The over current protection circuitry is active upon startup (short circuit protection is not). During soft−start, under normal conditions, the current limit circuit should not trip. However, with large output capacitance, the current limit circuit may determine the output voltage rise time instead of the soft−start circuit. To ensure that the output voltage is...
controlled by the soft–start circuit make \( dt_{\text{limit}} \leq T_{SS1} \), where \( T_{SS1} \) is the soft–start time and \( dt_{\text{limit}} \) is equal to:

\[
\frac{C_{OUT1} \times V_{OUT1}}{I_{\text{LIMIT}}} \quad (\text{eq. 3})
\]

**Overcurrent Protection (SMPS2)**

The current limit for SMPS2 is internally set at 3.05 A (typ). The operation is similar to SMPS1 in that it immediately ends the pulse upon overcurrent detection. This repeats every cycle until the overcurrent condition is removed. Similar to SMPS1, the over current protection circuitry is active upon startup.

As with SMPS1, short circuit protection is implemented with a comparator monitoring the feedback. If the output voltage goes below 70% of nominal after start–up, the part is latched off, requiring SYS_EN to be toggled to restart the part.

**Overcurrent Protection (LDO1 and LDO2)**

There are two overcurrent protection circuits incorporated; one provides a current limit feature, the other provides a short circuit protection feature. Under normal operation, the current is sensed through a sense resistor connected to ISNS[x]+ and ISNS[x]− and limited by the equation:

\[
I_{\text{LIMIT}(LDO)} = \frac{V_{\text{SNS}[x]}}{R_{\text{SNS}[x]}} \quad (\text{eq. 4})
\]

where, \( R_{\text{SNS}[x]} \) is the sense resistor for LDO1 and LDO2, and \( V_{\text{SNS}[x]} \) is the current limit threshold. To calculate \( R_{\text{SNS}[x]} \), the minimum \( V_{\text{SNS}[x]} \) value and the maximum operating current should be used.

**Overcurrent Protection (High–Side Load Switch)**

There are two primary protection features of the internal high–side 2.8 A (typ.) current limit. The first protection involves a short circuit condition during startup, and the second involves an overload condition after startup.

During startup, if the output does not exceed 4.5 V (typ.) in 1.5 ms (typ.), the device is considered to be in a “hard” short circuit condition, and is latched off. In addition, if the device does not exceed \( V_{\text{IN}} - 3.75 \text{ V (typ.)} \) in 3 ms (typ), the device is considered to be in a “soft” short circuit condition, and is latched off. Furthermore, if \( V_{\text{HS_S}} \) goes below \( V_{\text{IN}} - 3.75 \text{ V (typ.)} \) during normal operation, for more than 3 ms (typ), the device is considered to be in a “soft” short circuit condition, and is latched off. Once the high–side switch has been latched off, a HS_EN toggle will be required to reset it.

**Overvoltage Clamp (High–Side Load Switch)**

The source output of the high–side switch is clamped during a high battery condition. This protects any load connected to the source from seeing a double battery or load dump condition. If the input rises above 16 V (typ), the internal gate of the high–side switch will be pulled low to keep the source from rising. The high–side switch will operate in this linear mode until the input voltage exceeds 18.5 V (typ) at which point the entire IC will shutdown.

To thermally protect the pass device during a short circuit event, a comparator monitoring the feedback voltage is incorporated. If the output voltage goes below 70% of nominal (typ), the LDO will latch off. This is an independent operation, meaning, a short circuit on one LDO does not affect the operation of the other, nor does it affect the SMPS or high–side switch. An LDO_EN toggle is required to re–start an LDO if it latched off due to a short circuit event.

In addition, the current limit should be chosen such that the output voltage will rise to greater than 70% of the final \( V_{OUT} \) within 2.74 ms in order to keep the short–circuit circuit from falsely tripping.

**APPLICATION INFORMATION**

**Setting the Output Voltage**

To set the output voltage of any of the controllers or regulators, use the following equation:

\[
V_{\text{OUT}[x]} = V_{\text{REF}} \left(1 + \frac{R_1}{R_2}\right) \quad (\text{eq. 5})
\]

where, \( R_1 \) is the resistor that is connected from \( V_{OUT}[x] \) to the feedback pin of its respective channel and \( R_2 \) is connected from that feedback pin to ground. To reduce the effect of input offset current error, it is customary to calculate \( R_1 \) with \( R_2 \) equal to 1 kΩ.

**LDO1 and LDO2 Pass Device Selection**

The LDO controllers have been optimized to give the best performance with the NTD20P06L p–channel MOSFET. While other p–channel MOSFET can be used, specifications in the electrical table are guaranteed only with the NTD20P06L, and using a different MOSFET may require external compensation to stabilize the output. The NTD20P06L can be used as the pass device for both controllers, and is rated with a ~60 V max \( V_{DS} \). This device comes in two different packages allowing great flexibility.
when designing the thermal solution. The IPAK package can be attached to the radio’s metal enclosure or it can be attached to an independent heatsink. If output current demands are low, then a DPAK package can be used for a surface mount solution.

**LDO Output Capacitor Selection**

The LDO controllers have been optimize and compensated to work with a variety of output capacitors. Aluminum electrolytic capacitors with an ESR up to 5 Ω to ceramic capacitors with an ESR down to 10 mΩ can be used. Depending on load requirements, the output capacitor can range from 10 µF to as much as 100 µF. There are many capacitor vendors which supply automotive rated parts that fall within these ranges. For example, the Nichicon UD or PM type capacitors are suited well for the LDO controllers and automotive radio application. Values outside of these ranges can be used, but may require external compensation.

**SMPS1 MOSFET Selection**

SMPS1 has integrated MOSFET drivers optimized for driving N-channel MOSFETs in a synchronous buck configuration. The lower MOSFET driver is designed to drive a ground-referenced low R_DS(ON) n-channel MOSFET. The supply rail for the lower driver is internally connected to DRV_VPP and the PGND pin is it’s ground reference. The upper MOSFET driver is a floating gate driver designed to drive low R_DS(ON) n-channel MOSFETs. A bootstrap circuit referenced to SN1 as shown in figure 1 develops the supply rail for the upper MOSFET driver.

The driver circuitry includes non-overlap protection. The non-overlap protection prevents both Q1 (upper MOSFET) and Q2 (lower MOSFET) from being on at the same time, and minimizes the associated off times.

This helps reduce power losses in the switching elements. The non-overlap protection circuit accomplishes this by controlling the delay from Q1’s turn-off to Q2’s turn-on, and from Q2’s turn-off to Q1’s turn-on by monitoring the voltage at the SN1 and GL1 pins. When the internal PWM signal goes low, GH1 will go low, turning Q1 off. However, before Q2 can turn on, the non-overlap protection circuit waits for the voltage at GL1 to fall below 1.8 V. Once SN1 falls below the 1.8 V threshold, GL1 will go high, turning Q2 on. However, the safety timer circuit will override the normal control scheme and drive GL1 high. This will help insure that if Q1 fails to turn off it will not produce an over-voltage at the output.

Similarly, to prevent cross conduction during Q2’s turn-off and Q1’s turn-on, the non-overlap circuit monitors the voltage at the gate of Q2 through the GL1 pin. When the internal PWM signal goes high, GL1 will go low turning Q2 off. However, before Q1 can turn on, the non-overlap protection circuit waits for the voltage at GL1 to drop below 2 V. Once this has occurred, GH1 will go high, turning Q1 on.

For the DRV_VPP supply, a local bypass capacitor is not only required for stability, but also to reduce noise and supply peak currents during operation. Use a 1 to 4.7 µF, low ESR capacitor. Multilayer ceramic chip (MLCC) capacitors provide the best combination of low ESR and small size. This capacitor must be referenced to PGND. The bootstrap circuit comprises a charge storage capacitor (C_{BST1}) and the internal bootstrap diode. Typical C_{BST1} values range from 100 nF to 1 µF. The average forward current can be estimated by the following equation:

\[ I_{BST1} = Q_{GATE} \times FSW \]  

where, \( Q_{GATE} \) is the total gate charge. The average forward current through the internal diode should not exceed its rated maximum of 12 mA. This puts a limitation on the MOSFETs used at a particular switching frequency.

The power dissipation for the internal MOSFET drivers can be calculated using the following equation:

\[ P_{d_{GP1\_drv}} = P_{d_{GH1\_drv}} + P_{d_{GL1\_drv}} \] (eq. 7)

\[ P_{d_{GH1\_drv}} = Q_{GH1} \times V_{GH1} \times FSW \] (eq. 8)

\[ P_{d_{GL1\_drv}} = C_{GL1} \times (V_{GL1})^2 \times FSW \] (eq. 9)

where, \( Q_{GH1} \) is the total gate charge of the upper MOSFET, \( C_{GL1} \) is the total input capacitance of the lower MOSFET, \( V_{GH1} = V_{GL1} = 7.2 \ V \) (typ.) which is the DRV_VPP output voltage.

One method to improve the IC power dissipation is to use the 8 V SMPS output to the DRV_VPP pin. This will reduce the internal regulator and the IC will run from the SMPS output. Doing this will incrementally increase the gate drivers power dissipation, but will reduce the loss associated with the DRV_VPP running from battery.

For example, if the DRV_VPP is operating at 12 mA from a 14.4 V battery to power SMPS1’s gate driver circuit, the power dissipation from this will be 90 mW. In addition, with a 20 nC GH1 change and a 1.8 nF GL1 capacitance, the gate driver loss will be 80 mW. This is a total of 170 mW of power dissipation due to running the gate drivers at 340 kHz. However, if there was a diode—or the 8 V SMPS output to the DRV_VPP pin. This will reduce the SMPS losses, and the total power dissipation from the SMPS1 gate drivers reduce to 95 mW. The improvement gets better when accounting for SMPS2’s gate driver loss. These savings can be proven to be beneficial in fast FSW and high current applications.

There are two recommended n-channel MOSFET for SMPS1, the NTD24406, which has a 60 V max VDS, and the NTD5407N, which has a 40 V max VDS. Determining which MOSFET to use is predicated by the load dump requirements. The same device can be used for the upper and lower MOSFET. The benefit of this is reduced cost due to economies of scale.
SMPS2 Diode Selection

The diode in SMPS2 provides the inductor current path when the power switch turns off. This is known as the non-synchronous diode or commutation diode. The peak reverse voltage is equal to the maximum operating input voltage. The peak conducting current is determined by the internal current limit. The average current can be calculated from:

\[
I_{D(\text{avg})} = I_{\text{OUT2}} \left(1 - \frac{V_{\text{OUT2}}}{V_{\text{INW}}\text{SW}}\right) \quad (\text{eq. 10})
\]

However, the worse case diode average current occurs during a short circuit condition. For a diode to survive an indefinite short circuit condition, the current rating of the diode should be equal to the maximum current limit which is 3.6 A. Thus the MBRS4201T3 is the diode of choice.

Inductor Selection

Both mechanical and electrical considerations influence the selection of an output inductor. From a mechanical perspective, smaller inductor values generally correspond to smaller physical size. Since the inductor is often one of the largest components in SMPS system, a minimum inductor value is particularly important in space-constrained applications. From an electrical perspective, smaller inductor values correspond to faster transient response. The maximum current slew rate through the output inductor for a buck regulator is given by:

\[
\text{Inductor Slew Rate} = \frac{dI_L}{dt} = \frac{V_L}{L} \quad (\text{eq. 11})
\]

Where \( I_L \) is the inductor current, \( L \) is the output inductance, and \( V_L \) is the voltage drop across the inductor. This equation indicates that larger inductor values limit the regulator’s ability to slew current through the output inductor in response to output load transients. Consequently, output capacitors must supply (or store) sufficient charge to maintain regulation while the inductor current “catches up” to the load. This results in larger values of output capacitance to maintain tight output voltage regulation.

In contrast, smaller values of inductance increase the regulator’s maximum achievable slew rate and decrease the necessary capacitance, at the expense of higher ripple current.

In continuous conduction mode, the peak–to–peak ripple current is calculated using the following equation:

\[
I_{\text{PP}} = FSW \frac{V_{\text{OUT}}}{L} \left(1 - \frac{V_{\text{OUT}}}{V_{\text{BATT}}}\right) \quad (\text{eq. 12})
\]

From this equation it is clear that the ripple current increases as \( L \) decreases, emphasizing the trade–off between dynamic response and ripple current.

For most applications, the inductor value falls in the range between 2.2 \( \mu \text{H} \) and 22 \( \mu \text{H} \). There are many magnetic component vendors providing standard product lines suitable for SMPS1 and SMPS2’s requirements. TDK offers the RLF12545–PF series inductors, which are recommended for the automotive radio application.

SMPS Output Capacitor Selection

The output capacitor is a basic component for the fast response of the power supply. In fact, during load transient, for first few microseconds they supply the current to the load. The controller recognizes the load transient and proceeds to increase the duty cycle to its maximum. Neglecting the effect of the ESL, the output voltage has a first drop due to the ESR of the bulk capacitor(s).

\[
\Delta V_{\text{OUT(ESR)}} = \Delta I_{\text{OUT}} \times \text{ESR} \quad (\text{eq. 13})
\]

A lower ESR produces a lower \( \Delta V \) during load transient. In addition, a lower ESR produces a lower output voltage ripple.

The voltage drop due to the output capacitor discharge can be approximated using the following equation:

\[
\Delta V_{\text{OUT(discharge)}} = \frac{(\Delta I_{\text{OUT}})^2 \times L}{2 \times C_{\text{OUT}} \times (V_{\text{IN(min)}} \times D_{\text{MAX}} - V_{\text{OUT}})} \quad (\text{eq. 14})
\]

where, \( D_{\text{MAX}} \) is the maximum duty cycle value, which is 90%. Although the ESR effect is not in phase with the discharging of the output voltage, \( \Delta V_{\text{OUT(ESR)}} \) can be added to \( \Delta V_{\text{OUT(discharge)}} \) to give a rough indication of the maximum \( \Delta V_{\text{OUT}} \) during a transient condition. Simulation can also help determine the maximum \( \Delta V_{\text{OUT}} \); however, it will ultimately have to be verified with the actual load since the ESL effect is dependent on layout and the actual load’s \( \text{di/dt} \).

SMPS Input Capacitor Selection

The primary consideration for selecting the input capacitor is input RMS current. However, since there are two SMPS running out–of–phase with each other, calculating the input RMS current can be complicated. The graphs below show how the input RMS current is affected by differing phase angles between SMPS1 and SMPS2. The plot below was generated with \( V_{\text{OUT1}} \) at 5 V with a load of 2 A and an output inductor value of 10 \( \mu \text{H} \), and \( V_{\text{OUT2}} \) at 8 V with a load of 4 A and an output inductor value of 10 \( \mu \text{H} \).

Figure 22. Irms vs Phase
Here it is shown that the “sweet spot” phase angle (where the input RMS current is the lowest) happens at the same location (in terms of phase relationship) regardless of input voltage. Thus, once the output voltages are known, a sweet spot can be determined. After determining the sweet spot, the input capacitors can be chosen accordingly to handle the RMS current.

The purpose of interleaving the two SMPS is to eliminate any overlapping of their input currents. This will reduce the overall input RMS current. Since the outputs are running at different voltages, they will have different duty cycles, and thus running with 180° phase difference does not necessarily guarantee an optimal input RMS current reduction. The figures below describe, graphically, this point.

To achieve this optimization, the SYNC function on the NCV8855 will have to be used with a 40% duty cycle clock. However, when looking at the worst-case input RMS (which occurs at high battery) a 40% duty cycle clock will yield the same input RMS current as a 50% duty cycle clock. Thus, the only true benefit of this optimization occurs when a narrow input voltage range is assured. Therefore, a 50% duty cycle clock is always recommended.

SMPS Compensation

The NCV8855 utilizes voltage mode control. The control loop regulates VOUT by sampling VOUT and controlling the duty cycle. Inherent with all voltage-mode control loops is a compensation network.

The compensation network consists of the internal error amplifier and the impedance networks ZIN (R1, R3 and C3) and ZFB (R2, C1 and C2). The compensation network has to provide a closed loop transfer function with the highest 0 dB crossing frequency to have fast response and the highest gain in dc conditions to minimize the load regulation. A stable

http://onsemi.com
control loop has a gain crossing with $-20$ dB/decade slope and a phase margin greater than $45^\circ$.

![Diagram](http://onsemi.com)

To reiterate, there are 3 primary goals to compensating. Goal 1 is to have a high a unity gain bandwidth (UGB) that is greater than $1/10$ the switching frequency, but less than $1/2$ the switching frequency. UGB is also known as the crossover frequency. This is the point where the closed loop gain $= 0$ dB or a gain of 1. In the plot above, the UGB is the point where the red line crosses the $\Omega$ axis. Goal 2 is to have the closed loop gain cross 0 dB with a $-20$ dB/decade slope also known as a $-1$ slope. Goal 3 is to achieve over $45^\circ$ of phase margin when the gain crosses 0 dB.

These are just goals. Sometimes the crossover frequency is reduced below $1/10$ FSW in order to meet goal 3. Conversely, some designs will push the crossover frequency as high as it can (as long as it is below $1/2$ FSW) with a reduce phase margin of $30^\circ$ in order to get a faster transient response. The only two absolutes are that the crossover frequency cannot exceed $1/2$ FSW and the phase margin has to be greater than $0^\circ$ at crossover. However, a SMPS operating towards these absolutes will experience severe ringing before it dampens out.

To achieve the above goals, the following guidelines should be adopted.
- Place $w_{Z1}$ at half the resonance of $w_{LC}$
- Place $w_{Z2}$ at or around $w_{LC}$
- Place $w_{P1}$ at $w_{ESR}$
- Place $w_{P2}$ at half the switching frequency

Performing these calculations will take some amount of iterations and bench testing to verify results. However, ON Semiconductor has developed a tool to speed up the design process tremendously with great ease and accuracy. This tool can be downloaded by following the below link.
